**Early Online Release:** This preliminary version has been accepted for publication in *Bulletin of the American Meteorological Society*, may be fully cited, and has been assigned DOI 10.1175/BAMS-D-20-0102.1. The final typeset copyedited article will replace the EOR at the above DOI when it is published.

## Main

10

11 In early December 2019, an outbreak of the novel coronavirus pneumonia (COVID-19)

12 occurred in Wuhan, Hubei province, China and has fast spread to the whole China. As

13 of 15 June 2020, there have been about 84 thousand confirmed cases over China.

14 Chinese government launched the national emergency response upon the detection of

15 the COVID-19 in Wuhan. To curb the spread of the epidemic, the outbound channels

16 of Wuhan have also been closed since January 23 2020 (Li et al. 2020; Xinhua 2020).

17 On January 26, the second day of the Lunar Chinese New Year, all the motor vehicles

18 were banned in urban central Wuhan, except for special vehicles to supply epidemic

19 prevention (Government 2020). In terms of the national prevention and control

20 measures, the government encouraged people to stay at home; discouraged mass

21 gatherings; extended the Lunar New Year holiday; closed all cross-province bus

22 services and closed schools, government offices, and factories (Chen et al. 2020).

23 The nationwide anti-virus battle in China brought great changes to personal daily-life

24 and society operation, and caused a huge challenge to some sensitive sectors, including

25 transportation, tourism, retail and entertainment, which leads to GDP decreased by 6.8%

26 in the first quarter of 2020 (Statistics 2020). But on the other hand, many regions in

27 China are suffering from severe air pollution in recent years. A drastic drop of air

28 pollutant emissions occurring with the national lockdown improved the human living

29 environments greatly (NASA 2020). The nationwide lockdown can be considered as an

30 ideal and unique field experiment for the prevention and control of current severe air

31 pollution. It is still unclear that how does the air quality change during the lockdown

32 period and what should we learn about air pollution mitigation from this nationwide  
33 ideal experiment.

#### 34 **Air quality variations during COVID-19 epidemic**

35 Giving the effect of city vehicles, air quality within two months after January 26 (i.e.,  
36 “AF1 period”: 1/26/2020 ~ 2/25/2020 and “AF2 period”: 2/26/2020 ~ 3/27/2020) are  
37 compared with that within one month before January 23 (i.e., “BF”: 12/23/2019 ~  
38 1/22/2020), respectively. The corresponded historical average air quality data of BF,  
39 AF1 and AF2 (i.e., His\_BF: 12/23 ~ 1/22 of 2013 to 2018; His\_AF1: 1/26~2/25 of 2014  
40 to 2019; His\_AF2: 2/26~3/27 of 2014 to 2019) are involved to show the relative  
41 variation of air quality during the nationwide lockdown. The response of air quality to  
42 the epidemic are evaluated at provincial scale, because the detailed lockdown measures  
43 have regional difference according to the severity of local epidemic.

44 According to the corresponding historical averages of air quality during each month of  
45 BF, AF1 and AF2 period in Fig. S1, air quality has obvious monthly variations in most  
46 parts of China (e.g., PM<sub>2.5</sub> concentration in Hist\_BF period is higher than that of  
47 Hist\_AF1 and Hist\_AF2 period). To avoid the effect of air quality monthly variations,  
48 the air pollutants concentrations in BF, AF1 and AF2 period are normalized relative to  
49 their historical averages. It can be found that, except for O<sub>3</sub>, the concentration of other  
50 air pollutants from BF to AF2 period are lower than their historical average (c.f., Fig.  
51 S1), with the normalized concentrations lower than 100%, indicating the achievements  
52 of recent air pollution mitigation in China. As shown in Fig. 1, the normalized air

53 pollutants concentrations are generally lowest in AF1 period, and then redounds  
54 partially in AF2 period. As far as national average is concerned, PM<sub>2.5</sub>, PM<sub>10</sub>, SO<sub>2</sub>,  
55 CO, NO<sub>2</sub> and O<sub>3</sub> concentrations show remarkable variations compared with those of  
56 historical averages, with -27%, -36%, -52%, -27%, -40% and 15% changes during the  
57 first month of lockdown period, and -32%, -30%, -48%, -38%, -29 and 2% change  
58 during the second month of lockdown period. The Chinese government rolled out the  
59 most ambitious and aggressive disease containment effort in AF1 period. While, some  
60 unnecessarily tough measures restricting economic activities were stopped with the  
61 decrease in daily confirmed new COVID-19 cases in AF2 period (Tian et al. 2020),  
62 which may cancel out the effect of lockdown on air quality.

63 In general, it shows more notable variations in air quality during AF1 period than that  
64 of AF2 period. Thus, we will go through some detailed air quality variation in AF1  
65 period here. Provinces with the lowest five normalized air pollutant concentration  
66 (highest for O<sub>3</sub>) during AF1 period are listed in Fig. 1. Most of the exhibited provinces  
67 are the hardest hits by COVID-19 with more than 500 confirmed cases, which proves  
68 the effects of disease prevention and control measures on air quality in China. With the  
69 strictest anti-virus measures during pandemic, PM<sub>2.5</sub>, PM<sub>10</sub> and NO<sub>2</sub> concentration  
70 decreased significantly by approximate 52%, 51% and 54% along with 30% increase  
71 in O<sub>3</sub> when compared AF1 with its historical period in Wuhan. In addition to Wuhan,  
72 the provinces of Zhejiang, Jiangxi, Hunan and Hubei are in the top five lists of AF1  
73 PM<sub>2.5</sub> concentration decrease, with 49%, 47% and 45% decrease compared with  
74 historical average, the descent scopes of which are higher than those of BF period.

75 Provinces with remarkable reduction in PM<sub>2.5</sub> concentration also show significant  
76 decrease in PM<sub>10</sub> concentration by 49% to 54%. Approximate 65% of provinces and  
77 areas in China show normalized PM<sub>2.5</sub>/PM<sub>10</sub> concentrations lower than 80%/70% in  
78 the period of AF1, however, Beijing, Tianjin and surrounding areas have relatively high  
79 normalized particulate pollution concentrations of about 100% for PM<sub>2.5</sub> and 70~80%  
80 for PM<sub>10</sub>. In terms of SO<sub>2</sub>, its major anthropogenic source is thermal power plants,  
81 industry and residential emission in China (Zheng et al. 2018). According to the low  
82 normalized concentration in BF period, SO<sub>2</sub> concentration shows significant decrease  
83 over the whole China in recent years, especially over northern China, indicating the  
84 importance of coal desulfurization and nationwide emission reduction. Giving the AF1  
85 period, the decreasing extents of SO<sub>2</sub> concentrations over Beijing, Tianjin and Henan  
86 Provinces are more significant than other regions. CO is mainly originated from the  
87 direct emission of industry, residential and transportation. It shows lower CO  
88 concentrations in AF1 period, with normalized concentrations lower than 100% over  
89 all the regions, but its decline rate is not as obvious as other air pollutants, with the most  
90 significant decrease of 40% over Shaanxi, Shanxi and Henan Provinces.

91 As for NO<sub>x</sub>, transportation, industry and power plant are its major anthropogenic  
92 emission source in China. Although lots of efforts have been taken to improvement air  
93 quality, the decrease trend of nationwide NO<sub>2</sub> concentration is weak in recent years,  
94 with the national average normalized NO<sub>2</sub> concentration of 89% in BF period, i.e., 11%  
95 decrease compared with historical average. Whereas, when the COVID-19 outbreak,  
96 remarkable NO<sub>2</sub> decrease of more than 55% over some hardest hits, e.g., Hubei,

97 Zhejiang, Henan and Hainan Provinces. Comparing with His\_AF1, NO<sub>2</sub>  
98 concentrations decreased by above 30% during AF1 period over approximate 78% of  
99 the country, and even the lowest decrease rate reach to 18.5% over Qinghai Province.  
100 Considering the case of O<sub>3</sub>, the concentration of which is driven by two major classes  
101 of directly emitted precursors, i.e., NO<sub>x</sub> and volatile organic compounds (VOCs).  
102 Except for the Guangxi Province, O<sub>3</sub> over the other provinces and areas increased  
103 significantly with the outbreak of coronavirus. The normalized O<sub>3</sub> concentrations range  
104 from 81~116% in BF period, which turns to 99~134% in AF1 period. Wuhan, Tianjin  
105 and the province of Shanxi show the most significant increase in O<sub>3</sub> concentration  
106 during AF1 period, with more than 30% increase compared with historical average. The  
107 current O<sub>3</sub> production over most urban regions of China is considered to be VOC-  
108 limited (Li et al. 2019). The opposite trend between O<sub>3</sub> and other air pollutants is  
109 inferred to be connected with the concurrent decrease of NO<sub>2</sub>. In addition, the obvious  
110 reduction of particulate pollutants leads to more solar radiation reaching to the surface,  
111 which benefits for the photochemistry and O<sub>3</sub> production.

## 112 **Effect of Meteorological elements**

113 It has been recognized that local ambient air quality is driven by both air pollutants  
114 emission and meteorological conditions. How did the meteorological elements behave  
115 during epidemic period? Two atmospheric dynamic indexes (i.e., 10 m wind speed,  
116 vertical wind shear between 500 and 850 hPa) and two thermodynamic indexes (i.e.,  
117 potential temperature difference between 850 and 1000 hPa ( $\Delta\theta$ ), surface relative

118 humidity ( $RH$ ) are involved to evaluate the meteorological conditions during AF1  
119 period, which have been verified in our previous work (Zhang et al. 2014). Fig. 2 shows  
120 the relative difference of the above four indexes between AF1 and His\_AF1 period.  
121 Generally, lower surface wind speed, lower vertical wind shear, higher  $\Delta\theta$  and higher  
122  $RH$  are more unfavorable for the diffusion of surface air pollutants. Extensive  
123 unfavorable conditions in surface wind speed and vertical wind occurred in AF1 period  
124 comparing with its historical average. It shows a north-south  $\Delta\theta$  dipole pattern over  
125 mainland China, which indicates a favorable vertical diffusion ability for air pollutants  
126 in southern China.  $RH$  during AF1 period are higher than that of His\_AF1 by at least  
127 20% over Beijing and surrounding regions. When taking  $\pm 10\%$  difference as a  
128 threshold of significance, the number of significant unfavorable indexes shown in Fig.  
129 2 (A) indicates Beijing, Tianjin and the northeast Liaoning Province experienced three  
130 more significantly unfavorable indexes for air pollutants simultaneously in AF1 period,  
131 followed by Hebei, Shanxi, Shandong, Sichuan, Qinghai, Guizhou, Xizang Provinces  
132 and Chongqing with two unfavorable indexes. Except for Beijing and Tianjin, most of  
133 the provinces and regions with remarkable variation in air quality displayed in Fig. 1  
134 did not show significant favorable or unfavorable meteorological diffusion conditions  
135 for air pollutants during AF1 period, which indicates the variations in air pollutant  
136 concentrations can be attributed to the changes of anthropogenic activities during the  
137 lockdown. However, the unfavorable atmospheric horizontal and vertical diffusion  
138 conditions working with the relative high humidity over Beijing and Tianjin regions  
139 are benefit for the accumulation of ambient air pollutants, hygroscopic growth and

140 secondary formation of particles, which may negate the effects of emission reduction  
141 in lockdown period.

142 Although China's air quality improved greatly due to the strict emission reduction  
143 measures in recent years, the government is still taking steps to win "the battle for blue  
144 sky". The variations in the nationwide air quality during COVID-19 should be  
145 referenceable in determining the goals of the future emission reduction policies. With  
146 the nationwide reduction of anthropogenic activities, the pollution of particulate matter,  
147 SO<sub>2</sub>, NO<sub>2</sub> and CO could be eased substantially, whereas, O<sub>3</sub> problem is obviously  
148 going to receive more attentions. The nationwide increase in O<sub>3</sub> concentration along  
149 with reduction in NO<sub>2</sub> demonstrates that O<sub>3</sub> production in China will always be in  
150 VOC-limited stage in the near future. The increase of particulate pollution in Beijing  
151 during the pandemic indicates air pollution episode may still occur with the unfavorable  
152 background meteorology, even if taking the emission reduction efforts as in COVID-  
153 19 period. It is worthy of deep consideration to keep the balance of improving  
154 particulate matter and O<sub>3</sub> pollution. In addition, as the domestic coronavirus epidemic  
155 getting controlled, China is already working to bolster its economy and restore the  
156 normal social operations in a stepwise fashion. Blue sky and economic development  
157 are equally important after work resumption taking place across China.

191

192

195 Fig. 1 Distribution of the confirmed COVID-19 cases by 02/25/2020 and normalized air pollutant  
 196 concentration in BF, AF1 and AF2 period. Provinces with the lowest five normalized air pollutant  
 197 concentration (highest for O3) during AF1 period are listed here. Asterisk (\*) in the label of x-axis  
 198 indicates the five selected provinces for the specific species. Air quality variation over the megacity,  
 199 Shanghai is also shown. Concentrations of Hubei province are the average of 12 cities excluding  
 200 Wuhan. Subplot titles are colored as the same color of the confirmed cases magnitude. Normalized  
 201 air pollutions concentrations relative to historical average are calculated as  $BF/His\_BF*100$ ,  
 202  $AF1/His\_AF1*100$  and  $AF2/His\_AF2*100$ , i.e., the normalized concentration lower than 100%  
 203 indicating the concentration during the specific period is lower than its historical average, and the  
 204 relative variation compared with historical average is  $(100\% - \text{normalized value})$ . Air quality dataset  
 205 can be obtained from the website of Ministry of Ecology and Environment of the People’s Republic  
 206 of China (<http://106.37.208.233:20035>).

209

210 Fig. 2 Relative difference of (A) 10 m wind speed, (B) vertical wind shear, (C) vertical potential

211 temperature ( $\Delta\theta$ ) and (D) surface relative humidity ( $RH$ ) between AF1 and His\_AF1 period (i.e.,212 values of  $(AF1-His\_AF1)/His\_AF1*100$ ). Vertical wind shear is defined as  $\sqrt{(u_{500} - u_{850})^2 +$ 213  $\sqrt{(v_{500} - v_{850})^2}$ .  $\Delta\theta$  is defined as  $\theta_{850} - \theta_{1000}$ , where  $\theta_{850}$  is the potential temperature at 850214 hPa. Positive difference of wind speed and wind shear as well as negative difference of  $\Delta\theta$  and215  $RH$  indicate more favorable meteorological conditions for air pollutants diffusion. Taking  $\pm 10\%$ 

216 difference as a threshold of significance, Fig. 2 (A) shows the number of significant unfavorable

217 indexes among the four indexes. Meteorological variables are download from ECMWF ERA5 with

218  $0.5^\circ*0.5^\circ$  resolution, which are average to provincial scale to evaluate the meteorological condition.

219
